Abstract
This report aimed to reveal the characteristics of calcifying panniculitis in two cats. Two biopsies taken from the lumbosacral region of an 8-month old and a 1-year old, male, mixed breed cats were evaluated. Macroscopically, there were masses of different sizes varying from 1.5 to 2.5 cm in diameter. The masses had a generally firmness and were grayish-white in colour. Histopathology revealed necrotic and degenerative lipocytes in lobules of subcutaneous fat tissue. In some areas, there were lymphocyte, macrophage and neutrophil leukocytes infiltrations and connective tissue proliferation. There were also large calcifying areas at the centre of degenerated-necrotic fat lobules. Alizarin Red S detected the calcifying areas and Masson’s trichrome differentiated connective tissue proliferation. In ABC-P, CD3 slightly reacted with lymphocytes and lymphoblasts. Vimentin moderately reacted with connective tissue proliferation at the periphery of the necrotic areas and the septum. A1AC reacted in the cytoplasm of macrophages and peripheral necrotic areas. No reaction was determined with A1AT. In conclusion, such cases have not been documented in veterinary pathology. It is believed that the two cats possibly had a renal deficiency problem or nephrotic syndrome in the pathogenetic mechanism. It was also considered that A1AC (serine proteinase inhibitor) expressions could have a role in such cases despite there being no A1AT (another serine proteinase inhibitor) expression.

Keywords: Calcifying panniculitis, Cat, Immunohistochemistry, Pathomorphology

INTRODUCTION
A panniculitis is a group of heterogeneous disease whose hallmark is inflammation of subcutaneous adipose tissue or panniculus adiposus. The inflammation frequently affects the deep dermis. In the etiology, there are generally infectious agents, foreign bodies, vitamin E deficiency, trauma, pancreatic disease, vasculitis, drug eruption and

lupus erythematosus in human beings. The disease may sometimes develop after steroid application, exposure to cold air or ice and α1-antichymotrypsin (A1AC), α1-antitrypsin (A1AT) deficiency, especially in humans. It has also been documented that the etiology of Weber Christian disease in humans remains unknown. The clinical classification of panniculitis has always been a problem in human dermatology, so classification has been performed on the basis of histological appearance. In medicine, these inflammatory changes of subcutaneous fat tissue can be classified in several types, although lobular (fat lobules), septal (interlobular septa including connective tissue) and diffuse (both fat lobules and septa) forms of panniculitis are found according to distribution in veterinary medicine [2]. The classification can be diversified into many types related to the etiology. Four main types have been defined as: 1) lobular panniculitis without vasculitis, 2) lobular panniculitis with vasculitis 3) septal panniculitis without vasculitis, 4) septal panniculitis with vasculitis [3]. Although calcifying panniculitis has been known since the 1980s, it is seen in the classification as a special topic [4-7]. That type of panniculitis has been generally reported in humans with renal failure and has primarily involved anticoagulant-like heparin injection sites [4,9]. The place of calcifying panniculitis has not been conclusive despite being known as a sub-class of lobular panniculitis without vasculitis [5,10]. It is a peculiar form of calcinosis cutis which belongs to the spectrum of calciphylaxis [4]. The most possible reason is the disturbance of the calcium-phosphate balance [5,12]. Macroscopically, lesions are seen as symmetrical violaceous to black patches or plaques. They frequently develop on the legs, and sometimes on the upper extremities and trunk. The lesions can be enlarged with necrotic and black eschar tissues. Over time, ulcers may open from those areas of subcutaneous necrosis. Microscopically, there is mucinous degeneration of fat tissue, lymphocytic vasculitis and adventitia and medial calcium deposits within adipose lobules of the interstitial connective region [4,7,10,11]. The aim of this report was to determine the different characteristics of calcifying panniculitis in two cats.

CASE HISTORY

Two brother cats, aged 8 months and 12 months old were brought to a private veterinary clinic with complaints of inappetence, depression and occasional jaundice. In clinical examination, there was seen to be cachexia and tenderness to abdominal palpation. The left lumbosacral region of the dorsal trunk in both cats was seen to be painful and partly ulcerated with eschar masses. Blood samples were collected from the cats and sent to a private veterinary laboratory for examination of blood parameters. It was then decided to remove the masses surgically and they were sent for diagnosis to the Pathology Department of the Veterinary Medicine Faculty of Ankara University. After macroscopic examination, tissue samples were taken from the lesions for histopathology examination. The samples were fixed in 10% formalin, processed routinely and embedded in paraffin. Sections were cut from the paraffin blocks of 5 μm thickness and stained with haematoxylin-eosin (H&E), Alizarin Red S and Masson's trichrome methods. After the histochemical staining, the indirect immunoperoxidase method (ABC-P) was applied using CD3, CD4, vimentin, alpha-1 antitrypsin and alpha-1 antichymotrypsin antibodies. The tissue sections were deparaffinized with xylene and rehydrated in decreasing dilutions of alcohol. Then, the sections were washed with phosphate buffered saline (PBS; pH 7.4). Endogenous peroxidase activity was blocked with 0.3% H2O2 for 20 min. The sections were processed with 0.1% trypsin at 37°C for 30 min. After the PBS washes, sections were incubated with protein blocking sera (Peroxidase Detection System, Novocastra, RE7110-K, Leica Biosystems). The sections were treated with primary antibodies (polyclonal rabbit alpha-1 antitrypsin-1/100, Abcam, monoclonal mouse anti-vimentin, clone V9, 1/100, Dako, polyclonal rabbit anti-alpha-1 antichymotrypsin-1/50, Abcam, polyclonal rabbit anti CD3 1/50, antibodiesonline, monoclonal mouse anti CD4, 1/100, Dako) in a humidified chamber for 1 h at room temperature. Then, biotinylated secondary antibody and streptavidin peroxidase complex (Peroxidase Detection System, RE7110-K, Novocastra, Leica Biosystems) were consecutively applied for 30 min each, and the section was washed 3 times with PBS between the applications. Control samples were treated with PBS instead of primary antibodies. As the chromogen, 3-amino- 9-ethylcarbazole (AEC) (Santa Cruz Biotechnology Inc.) was selected. Counterstaining was performed with Gill's haematoxylin. Sections were mounted with glycergel and examined under a light microscope (Leica).

Macroscopically, the mass had focal features of elastic consistency and was grayish-yellow in colour in the 8-month old cat. The mass weighed 1.5 g and measured 1.5x1.3x0.5 cm. In the elder cat, there were three masses of the same appearance as the first one. The masses weighed a total of 7 g and measured 2.5x1.5x1.3 cm, 1.5x2x1.2 cm, and 1.5x1x0.7 cm.

Microscopic examination revealed necrotic and degenerated fat cells in lobules of subcutaneous fat tissue (Fig. 1A-B). In some areas, lymphocyte, macrophage and neutrophile leukocyte infiltrations and connective tissue proliferation were observed. There were also large calcifying areas at the centre of the degenerated-necrotic fat lobules. Calcifying areas were detected with Alizarin Red S stain and connective tissue proliferation was detected with Masson's trichrome stain (Fig. 1C).

Immunohistochemical staining for CD3 slightly reacted with lymphocytes and lymphoblasts (Fig. 1D). Vimentin moderately reacted with connective tissue proliferation at the periphery of necrotic areas and the septum (Fig. 1E). A1AC reacted in the cytoplasm of macrophages and
peripheral necrotic areas (Fig. 1F). CD4 and A1AT were negative.

**DISCUSSION**

In these two cases, the clinical examination together with the results from the blood parameters suggested an inflammatory skin disease which may have been acute or subclinical in a disease connected to one of the internal organs. The anamnesis was useful for the clinician as vaccinations and parasite therapy had been administered to both cats 2.5 months and 1 month ago, respectively. However, the blood parameters demonstrated different results with low RBC, haemoglobin and high creatinine, calcium, phosphorus and WBC. From these results it was considered that a renal problem and anaemia may be related to eritropoetin dys-synthesis m. Pathomorphologically, lobular evaded necrotic adipocytes with severe inflammation in H&E staining and calcium deposits in Alizarin Red S staining and fibrocytic and fibroblastic proliferation in Masson’s trichrome staining revealed calcification in all the masses. Calcifying panniculitis has been reported in literature together with fatigue and a severe condition when considering calciphylaxis and nephrotic syndrome or renal failure in human counterparts [5,7,8,10]. However, despite the lack of appetite and mild cachexia, both cats appeared healthy and not in a serious condition. Histopathologically however, calcium deposits have not been reported to be dense on small or large vessels except on the interstitium although there have been a few reports [4,5]. Unlike other reports in literature and in humans, connective tissue proliferation was noticeable in this study and there was seen to be a tendency to granulomatous inflammation in one of the masses. Immunohistochemically, CD3 confirmed T-lymphocytes even though CD4 was negative for B-lymphocytes. Vimentin showed fibrocytic and fibroblastic proliferation developing at the periphery of necrotic areas. On the other hand, AAT was negative. ACT reacted in macrophages on the periphery of necrotic areas and between adipocytes and also in collagen bundles. In a few reports in recent years, emphasis has been placed on the relationship between alpha-1 antitrypsin (AAT) and alpha-1 antichymotrypsin (ACT) and panniculitis [13,14].

ACT and AAT are members of the serine protease inhibitor (serpin) superfamily of proteins. AAT plays a critical role by blocking the proinflammatory effect of neutrophil leukocytes. ACT also inhibits chymotrypsin-like serine proteases, with neutrophil cathepsin G thought to be the main target. It can also inhibit mast cell chymases and angiotensin-converting enzyme proteases which have a role in active vasoconstriction. Rajpara et al. reported that there is a relationship between overactivity of membrane bound serine proteases and neutrophil elastases in subcutaneous fat tissue. However, no immunohistochemical study was applied in terms of localization of positivities. In the current cases, AAT was applied and found to be negative, suggesting that there was no relationship between them, although it was considered that ACT might have a role in the pathogenesis of panniculitis. The ACT positivities from the cases can be considered to support that there is a connection between patients with renal failure and calciphylaxis.

In conclusion, this report is the first in respect of panniculitis classification in veterinary medicine in Turkey. It can be considered of guidance for researchers studying the role of serine protease inhibitors for other types of panniculitis cases in kidney-related disorders.
