Abstract
In this paper, clinical and neurological results of stabilization of a thoracic fracture and luxation with a pedicle screw-rod fixation system (PSRFS) in a dog have been reported. A physical and neurological examination revealed non-ambulatory paraparasis, upper motor neuron lesions of hind limbs which localized the lesion to thoracolumbal vertebra. On the radiographic survey; lateral views of the thoracolumbal region revealed luxation between Thoracal 11-12 (Th11-12) and fracture of end plate of Th11. After laminectomy and discectomy, two Ø 3.5 mm polyaxial pedicle screws were placed to each side of Th11-12 corpus and connected with a rod. The dog was able to stand without any support and was ambulatory with assistance after 6 weeks postoperatively. Full recovery was seen and normal alignment of the luxated vertebrae and fusion was seen on radiographic views on postoperative 6th month. As a conclusion PSRFS can be successfully used in fractures/luxations of vertebra in large breed dogs. The main disadvantages of the PSRFS are higher cost, limited screw dimensions and variability of pedicle safe corridors.

Keywords: Dog, Pedicle screw, Vertebral fracture

INTRODUCTION
Fractures, luxation and/or subluxation of vertebral column are seen frequently in companion animals [1,2]. The common causes of vertebral trauma are vehicle accident, falls, bite wounds and gun shots. In general, surgical treatment is required for these kind of traumas and several surgical techniques have been described including vertebral body plating, external splinting, spinal process plating in combination with application of a Kirschner-Ehmer apparatus, composite fixation with pins or screws and polymethylmethacrylate (PMMA), stabilization with external fixation, spinal stapling, modified segmental spinal instrumentation and tension band stabilization [3-6].

In human medicine, spinal fracture and luxation, or instability related to disk disease and spinal stenosis have been treated with surgical decompression combined with pedicle screw-rod fixation system (PSRFS) [7,8]. The primary goal of PSRFS is stabilization of decompressed spinal segments and thereby achieving bony fusion of spinal segment [7,9]. In veterinary practice PSRFS has been used...
Treatment of Traumatic Thoracal ...

for stabilization of lumbosacral junction in degenerative lumbosacral stenosis [10,11].

The purpose of this paper is to report the clinical and neurological outcomes of stabilization of thoracal fracture and luxation with PSRFS, which has been used in traumatic instability of vertebra.

CASE HISTORY

Ten months-old, male Labrador Retriever was admitted to the Department of Surgery, following a motor vehicle accident. According to the owner, following the accident the dog was ambulatory and medical treatment including corticosteroid, analgesic and B complex vitamin was performed in referral clinic, however, it soon deteriorated and became non-ambulatory. According to neurological examination, non-ambulatory paraparasis, upper motor neuron lesions of hind limbs which localized the lesion to thoracolumbar vertebra. And also presence of deep pain sensation was detected. Direct radiography was carried out under anesthesia which was provided by diazepam (0.28 mg/kg, IV, Diazem 10 mg, Deva, Istanbul, Turkey) and propofol (3 mg/kg, IV, Propofol 1% 20 mL, Fresenius, Istanbul, Turkey). On the radiographic survey, lateral views of the thoracolumbar region revealed luxation between Thoracal 11-12 (Th 11-12) and fracture of end plate of Th 11 vertebra (Fig. 1). Computed tomography views were also obtained (Fig. 2).

The dog received methylprednisolone (20 mg/kg, IV, Prednol-L 250 mg amp., Mustafa Nevzat, Istanbul, Turkey) and cefazolin (20 mg/kg, IV, Cefozin 500 mg, Bilim, Istanbul, Turkey) and morphine (0.01-0.02 mg/kg, IV, Morfin HCl 0.01 g/mL, Osel, Turkey) before induction of anesthesia. The dog was premedicated with acepromazine (0.025 mg/kg, IV, Calmivet Solution 5 mg/mL, Vetaquinol, Paris, France). Anesthesia was induced with propofol (3 mg/kg, IV, Propofol 1% 20 mL, Fresenius, Istanbul, Turkey) given intravenously until the desired level of induction was achieved. A size 7-cuffed endotracheal tube was inserted, and isoflurane anesthesia was maintained at 1-2% via low flow, semi-closed-circuit technique at an oxygen flow rate of 1 L/min. The dog was aseptically prepared and placed in the ventral recumbence and a dorsal approach was performed as previously described [12].

Laminectomy had been performed between Th 11-12 vertebrae and the luxation was reduced by traction of vertebral bodies with hooks. Discectomy and removal of fractured end plate of Th 11 were done. Two Ø 3.5 mm polyaxial pedicle screws were placed to each side of Th 11-12 corpus and connected with a rod (Fig. 3). Cancellous bone graft, maintained from wings of ileum was placed to the intervertebral disc space.

A cast including PVC (polyvinylchloide) as a support material, which was extended from interscapular region to lumbar 5 was used for external support. The normal alignment of the vertebra was detected after the operation (Fig. 4). Fentanyl (10-20 µg/kg, IV, Fantanyl 50 µg/mL, Hameln, London, United Kingdom) was applied for post-operative analgesia. Cefazolin was continued every 12 h for one week after the operation. The dog was hospitalized

and examined daily for 6 weeks. During hospitalization, physical therapy was carried out by placing the patient into a custom made cart and each joint of both limbs were extended and flexed through their full range of motion following a thorough hydrotherapy massage every day. This therapy was carried out on a custom made designed cart. The hind limbs were supported with a sling. The cast was changed at 10 day intervals and removed 4 weeks after the operation.

The dog was able to stand without any support and was ambulatory with assistance after 6 weeks postoperatively. However, the gait of the pelvic limbs was moderately uncoordinated. Adequate fracture healing and stable implant was detected by radiography at the end of hospitalization. Clinical, neurological and radiographic examinations were done on the third and sixth month postoperatively. On reexamination three months postoperatively, the gait had almost returned to normal, however, slight proprioceptive deficit of effect leg was detected. However, on postoperative 6th month postoperatively, full recovery and normal alignment of the luxated vertebrae and fusion was seen on radiographic views (Fig. 5).

**DISCUSSION**

The fractures and/or luxations are generally seen at thoracolumbar region in dogs [1,5,13]. Involvement of end plate to the fracture or luxation is frequently seen in cats and dogs younger than one year. The closure of end plates in dogs is completed after 11-14 months [1]. In our case the localization of the luxation and end plate physeal fracture, and the age of the case were compatible with the reports.

In human medicine PSRFS has been used for treatment of spinal stenosis, spinal fractures/luxations, and degenerative disk disease [7,8]. The aim of the PSRFS is to improve deformity and stabilize the spine in its natural position until fusion has occurred and prevent further degenerative changes [7,9]. In veterinary literatures, PSRFS has been only used to stabilize lumbosacral region after laminectomy for treatment of degenerative lumbosacral stenosis in dogs [10,11,14,15]. Furthermore, the system was used to investigate fusion in lumbar vertebrae [16]. According to authors’ knowledge PSRFS has not been used to stabilize the fracture and luxation of spine in dogs.

Several methods have been described to stabilize

---

**Fig 3.** Dorsal view of PSRFS after it was applied

**Fig 4.** Lateral radiographic view of operation site after the PSRFS application

**Fig 5.** Lateral radiographic view of operation site on postoperative 6th month. The normal alignment of vertebra and the fusion were detected
the fracture and luxation of spine [3-6]. Generally at least two cranial and caudal vertebrae of the fracture should be stabilized [5,6,13]. Transpedicular screw fixation maintains a rigid anchorage of the screw to the vertebral body. This anchorage enables a secure three-dimensional positional control between the screw and the longitudinal elements, which can provide a restoration of normal stiffness even in short segmental (i.e. one or two-level) instrumentation [7]. The screws were applied to the corpus vertebrae of Th 11-12. According to the peroperative observation rigid fixation was achieved, even though one level instrumentation.

Meij et al. [14] reported that dorsal laminectomy and partial discectomy had changed the stiffness characteristics of the spine specimen in neutral zone without changing range of motion, however, in natural cases with degenerative lumbar spinal stenosis laminectomy and discectomy could decrease stiffness significantly in vivo. In the case the stiffness of the vertebral region was markedly decreased after discectomy and removal of fractured end plate. According to our peroperative observation it was determined that stiffness of fractured region has been obtained after application of PSRFS.

PSRFS has been designed for human vertebrae, so the dimensions of the screws are not suitable even for large breed dogs. The use of pedicle screws for adult humans led to fracture of the lateral and the medial wall of the pedicle. Pedicle screws for pediatric patients better fit for adult canine vertebral pedicle [14]. The pediatric pedicle screws which is Ø 3.5 mm diameter were successfully used for the dog in this case and it was determined that pediatric PSPFS systems are suitable for large breed dogs

The dimensions and shapes of the vertebrae are differed even though in same breed animals. This is the main problem for safe screw insertions and prediction of the screw dimensions [17]. Smolders et all indicated that CT-and/or MRI-based evaluation of the vertebral dimensions of both L7 and S1 is necessary for optimal screw insertion corridors for individual dogs [15]. Before the surgery CT images had been evaluated for pedicle dimensions to predict the dimension of screws dimensions. Because, in human PSRFS the dimensions of the screw are limited for animals and eventually, Ø 3.5 mm diameter screws which are pediatric for human patients were used according to evaluation of CT images.

The fracture healing was detected at the end of hospitalization by radiographic examination which is consisted with spinal fractures can heal in as short as a time as 4 weeks [16].

As a conclusion PSRFS can be successfully used in fractures/luxations of vertebrae in large breed dogs. The main disadvantages of the PSRFS are higher cost, limited screw dimensions and variability of pedicle safe corridors. Further studies with large amount of cases with fractures/luxations of vertebrae will give more successful and supportive information for the usage of PSRFS in veterinary neurosurgery.
