Abstract
Atresia coli is sporadically seen in calves and lethal unless intestinal patency is restored through surgery. While there are some reports of surgically corrected animals with atresia coli giving birth to healthy offspring, there is still controversy about treating such cases, since survival is not guaranteed and there is a chance of tainting the herd’s gene pool. This study aims to investigate the efficacy of colonoscopy in cases of atresia coli in determining the atresia type and evaluating the lumen. Nineteen calves of different breeds and sex between the ages of 1 to 15 days were included in the study. Colonoscopy duration, maximum distance of the endoscope from the anus and any discernible changes inside the lumen were recorded for each case. The technique was easy to use, required no anaesthesia or sedation and very informative about the condition of the mucosa. Definitive diagnosis of the atresia type using colonoscopy is not possible unless a complete blind end is seen and iatrogenic damage may be caused during the procedure. We believe its diagnostic use can provide the surgeon with data to select which procedure to use and help with prognosis.

Keywords: Atresia coli, Calf, Colonoscopy

INTRODUCTION
Atresia coli is one of the most commonly seen malformations in calves. The disorder is traditionally classified in 4 types [1] but only the first three types of atresia are commonly seen [2]. First type is stenosis, with or without an intact or perforated diaphragm, second is cord atresia and the third is blind end atresia [2]. Etiology of this condition has been theorized to involve disruption of the blood supply to the bowels through local or genetic factors, thus causing stenosis or atresia [3]. Early rectal palpation have been said to cause the malformation [4]
Colonoscopic Diagnosis of Atresia Coli...

Although there is also evidence to the contrary, suggesting that early palpation is safe [5,6]. Genetic inheritance of this disease is proposed, and there is proof of this for some breeds, like Holstein-Friesian [7], but it remains suspect in many others [2,3]. The clinical and epidemiological prevalence suggests that this condition may not be inherited in non-predisposed breeds [4].

The prognosis of this condition is poor and worsens with the passage of time [8], as the calves born with this malformation are incompatible with life unless intestinal patency is restored with surgery [1,4]. Affected calves have been known to produce healthy offspring after being surgically corrected [9].

The diagnosis of atresia coli was traditionally based on clinical examination and findings alone. Radiography have been used for diagnosis [10] and there is a report of using contrast radiography and ultrasonography [11] to diagnose the condition. Definitive diagnosis is made by exploratory laparotomy [12].

Colonoscopy is a minimally invasive method that could potentially help to the diagnosis of the condition and provides data in preoperative planning. This study aims to evaluate the viability of this technique in calves with atresia coli.

MATERIAL and METHODS

The study material consisted of calves that were brought to the Teaching Hospital of Animal Hospital of Ondokuz Mayis University, Faculty of Veterinary Medicine, and Department of Surgery between the years of 2016 and 2018. Animals that were unable to defecate since birth were included in the study regardless of breed and gender.

After learning patient history from the owners, physical examination of each patient was made in accordance to our routine patient exam protocol (which included heart rate, respiratory rate, capillary refill time, dehydration level, body temperature). The hemogram of each patient was evaluated from a blood sample taken from the jugular vein. The patient was then placed on lateral recumbence, rectum was lubricated with polyacrylamide gel and colonoscopy was performed without sedation or anaesthesia. A 1.4 m long flexible endoscope with a diameter of 8.5 mm (Aohua, LG-200) was used for colonoscopy. The endoscopies were recorded using an external TV card’s (AverTV) own media capture software.

The atresia types were only estimations based on endoscopic findings since diagnosis requires visualizing the intestines from the outside. If there was no mucosal wall or blind end to be seen and the endoscope could not be moved further due to narrowing of the lumen, the condition was classified as “suspected type 1 atresia”.

Although the lumen was stenotic, the condition was presumed to be atresia since no feces were present. If the canal tapered to a very narrow point where the endoscope could not fit through it was recorded as “suspected type 3” atresia, and if a blind end could be clearly visualized it was recorded as a “type 3” atresia.

Breed, gender, atresia type, colonoscopy duration, reach of the endoscope (length from the anus to the maximum possible colonoscopic exam site) and mucosal damage due to previous procedures (done by the owner or private veterinarians) or during the colonoscopy performed in our hospital were recorded for each patient. The presence of iatrogenic damage during colonoscopy was determined when the endoscope was being retracted, if the mucosa was intact upon entry but damaged and/or bleeding while retracting, it was considered to be iatrogenic damage.

RESULTS

The most common breed was Simmental (n=12) followed by Jersey (n=1), Holstein mix (n=4), Limousin (n=1) and Holstein (n=1). Ten calves were male and 9 were female. Ages of the calves at the time of presentation were between 2 and 15 (mean 5.31) days. The colonoscopy is considered to be completed when the endoscope could not be moved any further due to narrowing or upon encountering a blind end. The duration varied between 1’49” and 7’57” (4’53” on average).

There was some amount of mucus content in each colon that was evaluated; in the early cases, that were brought between 1-3 days had clear, bright mucus over their mucosa, the mucus was thicker and yellow in older (4-6 days old) cases and the last three calves (7, 13 and 15 days old) had very thick, almost solid chords or lumps of dried mucus in their lumen. Types of colon content are shown in Fig. 1.

Twelve calves were recorded as having “suspected type 1 atresia”, 3 with type 3 and 4 with suspected type 3 atresia (Fig. 2). Mucosal damage was seen in 16 calves during colonoscopy; 12 cases had varying degrees of damage due to previous catheterization attempts with various materials. Six of these were delayed cases and had complications (Cases 12, 13, 14, 16, 18, 19), 5 were acute (Cases 2, 6, 7, 11, 17) being brought to the hospital right after the attempts with only superficial injury to the mucosal lining. In one case, the catheterization attempt of the owner resulted in perforation of the blind end (Case 9). The iatrogenic damage with colonoscopy was caused in 4 cases (Cases 3, 8, 10, 15) by either pushing the endoscope without sufficient lubrication of the lumen or inserting it too forcefully. Iatrogenic damage caused either erythematous changes or superficial abrasions and bleeding on the colon mucosa. Examples of mucosal damage were shown in Fig. 3.
The breed, gender, time elapsed after birth, atresia type, mucosa condition and colonoscopy duration of each case was shown on Table 1.

**DISCUSSION**

The condition mostly occurs in Holstein-Friesians because of a homozygous recessive inheritance factor and is sporadically seen in other breeds [4]. In our study, most of the effected calves were Simmental; this is most likely due to the large number of Simmental breeders in the region of our hospital.

Despite being one of the most common malformations seen in calves, there is no consensus on the etiology or surgical treatment of atresia coli [4]. Surgical correction by means of anastomosis or colostomy has been suggested even though the survival rate is rather low and postoperative care is demanding [4]. There are valid points on not correcting the condition as it is not extensively known to be non-hereditary in most breeds so there is a chance of keeping the calf with defective hereditary traits in the herd. Also, considering the low survival rate and operation costs, the owner is taking a financial risk if the surgery is done. However, there are reports on having healthy calves from surgically corrected animals [9] and many owners that come to our hospital look favourably on surgical correction if every advantage and disadvantage of the operation is explained to them.

The diagnosis of atresia coli is usually easy, meconium is not passed through after birth and there is an anal opening,
Clinicians should suspect intestinal atresia. The condition is not immediately fatal so there is often enough time to get the animal to a reference hospital for diagnosis and treatment. In this study, some of the cases were brought in very late, suggesting the owners mistook the mucus coming from the anal opening for meconium. Furthermore, most of the cases that were brought (n=11) had already damaged colon mucosae with one blind...
end confirmed to be perforated, meaning the owners or practitioners tried to insert a catheter inside the atretic colon, which has a very fragile mucosal lining. In three cases, the mucosal damage was extensive and the mucosa had necrotic areas due to the passage of time after being traumatized. While the number of cases presented in this study may not reflect a larger group, they still suggest the fact that many calves will be brought to the hospital with traumatized mucosal ulcers. It is possible to see the blind end of the colon with direct radiography and ultrasonography, and one study shows that retrograde contrast radiography can reasonably show the atretic segment. Exploratory laparotomy is the definitive way to establish diagnosis and determine the atresia type. None of these techniques provide a way to noninvasively evaluate the colon mucosa, although one study investigated potential damage to the intestines through the use of biomarkers. Atresia coli surgery involves either performing a colostomy or an anastomosis of the intestines, and even after surgery, functional obstruction may block the flow of feces. Performing colonoscopy not only aids in diagnosis but during the surgical planning process, as seeing a necrotic, infected or obliterated colon segment during the surgery may call for euthanasia and prevent wasting valuable time and resources. Also it helps the surgeon decide in choosing colostomy over anastomosis for diagnosis, and the results of this study show that it can be used for diagnosis in calves.

Colonoscopy requires minimal experience, is cheap to perform, and does not require sedation or anaesthesia. Familiarizing with the technique requires only a few tries and it can be done in around 5 min. We believe colonoscopy should be used for diagnosis in atresia coli cases and is quite useful for pre-operative planning, aids in determining prognosis and explaining the condition to the owners. The only drawbacks are that endoscopy is not readily available in every clinic and its use is usually limited to reference hospitals and iatrogenic damage to the mucosa is possible during its use.
